Alcohol Awareness Month — April 2002

The National Council on Alcoholism and Drug Dependence (NCADD) has designated April 2002 as the 16th annual Alcohol Awareness Month. NCADD, in collaboration with CDC and other federal agencies and community organizations, will highlight the health risks associated with problem drinking and the importance of identification and intervention. The theme of this year's campaign is "Recovery: It's a Family Affair—and Everyone's Invited!"

April 11 is National Alcohol Screening Day; screening sites throughout the country will offer participants an educational presentation, a written screening questionnaire, and an opportunity to meet with a health-care professional. Online and telephone screening also will be available. Locations of screening sites are available at http://www.mentalhealthscreening.org/alcohol.htm, telephone, 800-405-9200. Press kits, fact sheets, and information about "Alcohol-Free Weekend" (April 5–7) are available at http://www.ncadd.org.

This issue of *MMWR* presents findings from the Behavioral Risk Factor Surveillance System regarding alcohol consumption among women of childbearing age in the United States, which indicate that frequent drinking and binge drinking during pregnancy continue to pose a risk to the healthy pregnancy outcomes of many women. CDC is conducting a comprehensive public health research program to prevent alcohol-exposed pregnancies and provide effective interventions for persons with fetal alcohol syndrome and other disorders caused by prenatal alcohol exposure. Information about CDC's programs and the health effects of prenatal alcohol exposure is available at http://www.cdc.gov/ncbddd/fas. Additional information is available at http://www.niaaa.nih.gov and at http://www.samhsa.gov.

Alcohol Use Among Women of Childbearing Age — United States, 1991–1999

Prenatal exposure to alcohol is one of the leading preventable causes of birth defects, mental retardation, and neurodevelopmental disorders in the United States (*1*). One of the national health objectives for 2010 is to decrease alcohol use among pregnant women to 94% (*2*). During 1991–1995, alcohol use by pregnant women increased substantially, and alcohol use by nonpregnant women of childbearing age increased slightly (*3*). To characterize trends in alcohol use among women of childbearing age, CDC analyzed representative survey data from the Behavioral Risk Factor Surveillance System (BRFSS) during 1991–1999. This report summarizes the results of the analysis, which indicate that the rate of any alcohol use (i.e., at least one drink) during pregnancy has declined since 1995. However, rates of binge drinking (i.e., ≥5 drinks on any one occasion) and frequent drinking (i.e., ≥7 drinks per week or ≥5 drinks on any one occasion) during pregnancy have not declined among nonpregnant women of childbearing age. Health-care providers should routinely screen women of childbearing age for alcohol use and counsel them about the adverse effects of alcohol use during pregnancy.

BRFSS is an ongoing, state-based, random-digit–dialed telephone survey of the noninstitutionalized U.S. civilian population aged ≥18 years. Data were analyzed for women aged 18–44 years in all 50 states. Women were asked about their

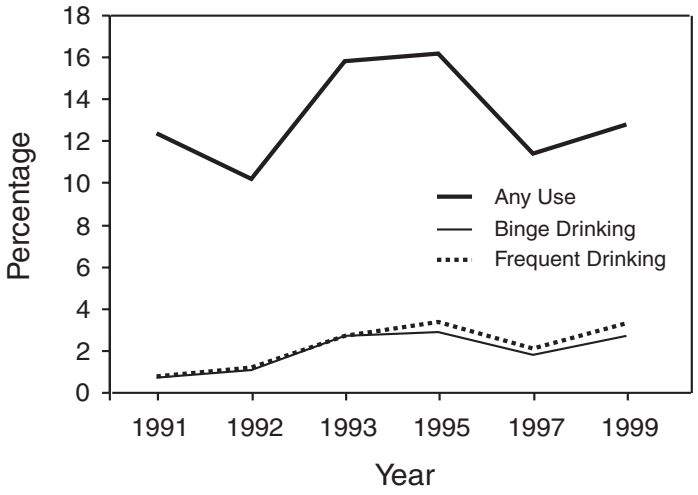
Centers for Disease Control and Prevention. [Article Title]. MMWR 2002;51:[inclusive page numbers].

use of alcohol during the 30 days preceding the survey. Three alcohol drinking patterns were examined: any use, binge drinking, and frequent drinking. Information on alcohol use was obtained every year through 1993 and every other year thereafter.

Sample data were weighted to reflect general population estimates, and standard errors were calculated by using SUDAAN. Linear regression models were used to examine temporal trends. To determine statistical significance, the inverse of the variance estimates was used for weights. Multivariate logistic analysis was conducted to examine the age, race, education level, employment, and marital status of pregnant and nonpregnant women by patterns of alcohol use. Because of the limited number of pregnant women surveyed, data were combined for 1995–1999 for the analysis of the characteristics of pregnant women who engaged in these risk behaviors.

During 1995–1999, a total of 4,695 (4.3%) of the 107,141 women aged 18–44 years who were interviewed about their alcohol use during the month preceding the survey reported that they were pregnant at the time of the interview. The prevalence of any alcohol use among pregnant women increased from 12.4% in 1991 to 16.3 % in 1995 (Figure 1) (*3*). Compared with 1995 data, prevalence was lower in 1997 (11.4%) and 1999 (12.8%). In contrast, the rates of binge drinking and frequent drinking reported by pregnant women in 1995 remained substantially unchanged in 1997 and 1999: binge drinking rates were 2.9% in 1995, 1.8% in 1997, and 2.7% in 1999, and frequent alcohol use rates were 3.5% in 1995, 2.1% in 1997, and 3.3% in 1999. Among nonpregnant

FIGURE 1. Weighted percentage of pregnant women aged 18–44 years who reported alcohol use — United States, 1991–1999*

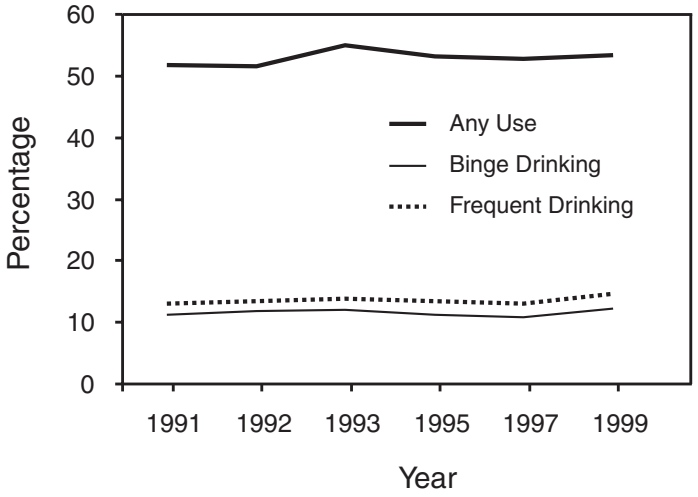


* Data not collected in 1994, 1996, 1998.

women who reported any alcohol use (Figure 2), rates remained stable: 53.2% in 1995, 52.8% in 1997, and 53.3% in 1999. Binge drinking rates among this population were 11.2% in 1995, 10.8% in 1997, and 12.3% in 1999.

In comparison with other pregnant women, pregnant women who reported any alcohol use, binge drinking, and frequent drinking were more likely to be aged >30 years, employed, and unmarried (Table 1). Nonpregnant women who reported any alcohol use, binge drinking, and frequent drinking had similar employment and marital status as pregnant women. In addition, nonpregnant women reporting any alcohol use were more likely to be white and to have higher education levels than women who did not engage in this behavior; nonpregnant women who reported binge drinking and frequent drinking tended to be aged <30 years.

FIGURE 2. Weighted percentage of nonpregnant women aged 18–44 years who reported alcohol use — United States, 1991–1999*



* Data not collected in 1994, 1996, 1998.

Reported by: *JS Sidhu, MD, RL Floyd, DSN, Div of Birth Defects and Developmental Disabilities, National Center on Birth Defects and Developmental Disabilities, CDC.*

Editorial Note: The findings in this report indicate that overall rates of any alcohol use during pregnancy declined since 1995. However, rates of binge drinking and frequent drinking during pregnancy did not decline and remain higher than the 2010 Healthy People objectives. These findings are consistent with those from the National Household Survey on Drug Abuse (*4*). Among nonpregnant women in their peak childbearing years, the use of alcohol, including the riskier practices of frequent and binge drinking, has not declined (*5,6*). Prenatal drinking patterns are highly predictive of alcohol use during pregnancy (*4*).

Pregnant women who are unmarried and older tend to have the highest rates of alcohol use (*4*). Women who drink alcohol are more likely than other women to be white, unmarried, younger, and working full time outside the home (*7*). Age is one characteristic that distinguishes heavier drinking patterns among pregnant and nonpregnant women. In this analysis, binge drinking and frequent drinking during pregnancy

were more common in women aged 30–44 years, but among nonpregnant women, these drinking patterns were more likely to occur among women <30 years. Women aged <30 years tend to reduce alcohol use when they become aware they are pregnant, but women aged ≥30 years are less likely to reduce alcohol use after learning they are pregnant (*5*), indicating greater alcohol dependency and difficulty in reducing or eliminating alcohol use during pregnancy (*8*).

The findings in this report are subject to at least three limitations. First, BRFSS data are self-reported and might be subject to reporting biases, especially among pregnant women who are aware that alcohol use is not advised. Second, because BRFSS is a telephone survey of the noninstitutionalized U.S. population, homeless women, women in homes without telephones, and women who are institutionalized were not surveyed. Both of these limitations could have an impact on prevalence rates. Finally, because the proportion of pregnant women in this sample who were drinkers was limited, these estimated prevalence rates are subject to variability.

Heavy alcohol use before pregnancy is highly predictive of continued use, chiefly among older prenatal patients. Because levels of binge and frequent drinking among nonpregnant women have not declined, all women of childbearing age should be warned about the adverse effects of alcohol use, especially high-risk drinking patterns (i.e., binge drinking and frequent drinking), and health-care providers should learn effective techniques for screening for, and intervening with, binge and frequent drinkers.

Routine screening can enhance women's present and future health and might avert early prenatal exposure before women become aware of pregnancy. Using brief intervention techniques and encouraging patients to seek social support through friends, family, and community groups might encourage women to abstain from alcohol use during pregnancy (*9*).

Potential disparities in health knowledge of pregnant women might be a contributing factor to sustained levels of binge and frequent drinking. To ensure more uniform dissemination of prenatal alcohol prevention messages, CDC, in collaboration with the Association of Schools of Public Health, will conduct targeted media campaigns to increase public awareness of the adverse effects of alcohol use during pregnancy among diverse geographic and racial/ethnic populations and among younger women.

Additional information about CDC's activities to prevent alcohol-exposed pregnancies is available at www.cdc.gov/ncbddd/fas.

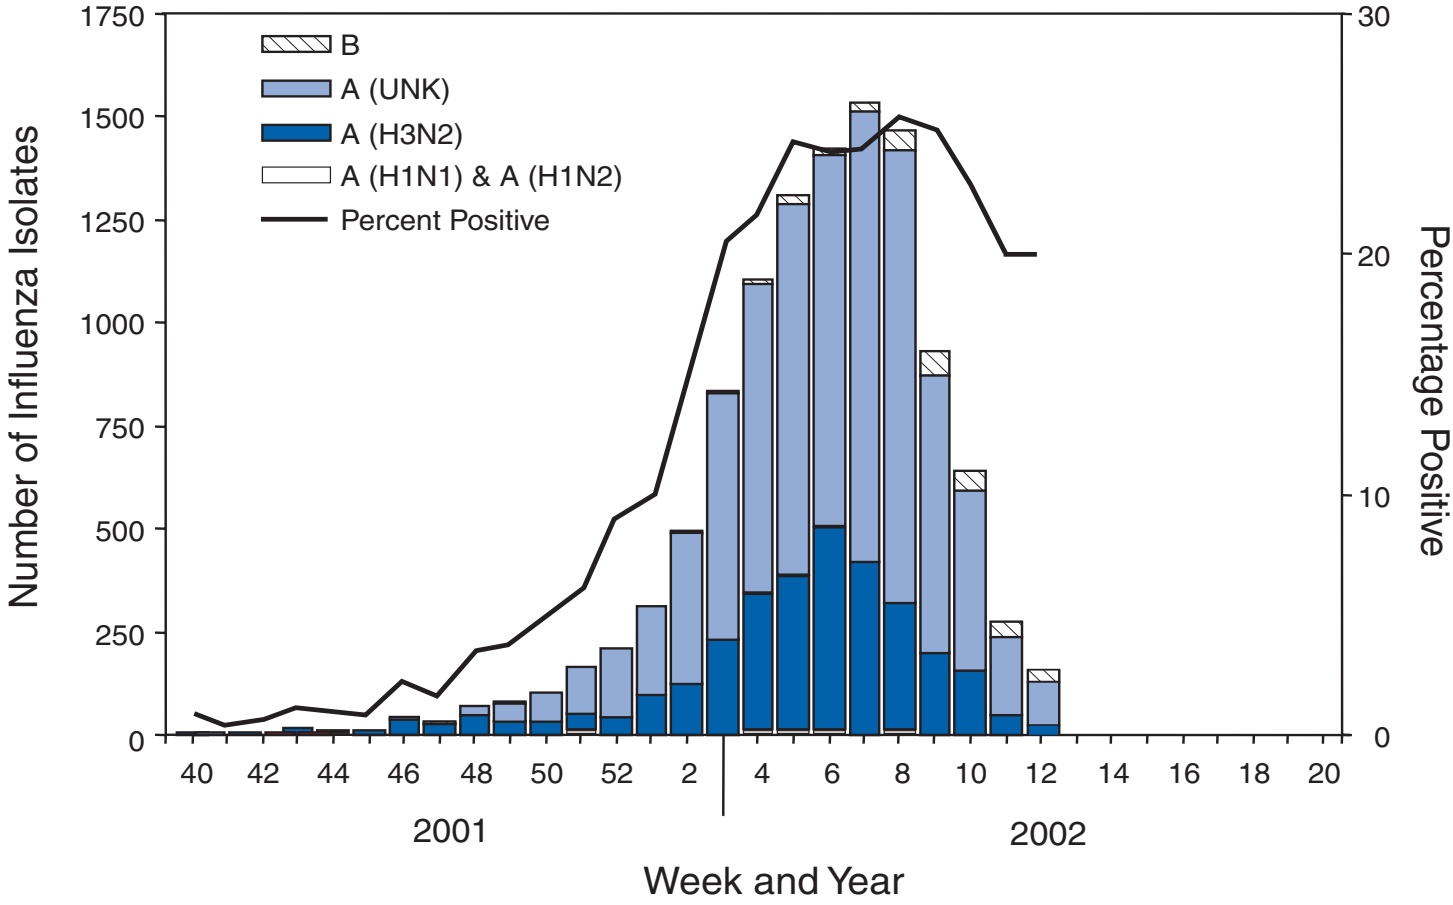
Update: Influenza Activity — United States, 2001–02 Season

Although data collected from the four components of the CDC influenza surveillance system* are preliminary, national influenza activity appears to have peaked during the week ending February 23, 2002 (week 8). During the 2000–01 and 1999–2000 influenza seasons, peak activity occurred during week 4 and week 51, respectively. The viruses most commonly isolated during the 2001–02 season have been influenza A (H3N2). These viruses were well-matched antigenically by the 2001–02 influenza A (H3N2) strain in the vaccine. This report summarizes influenza activity in the United States† during September 30, 2001–March 23, 2002, and updates previous summaries from this season (*1,2*).

For the weeks ending January 26 (week 4) through March 23 (week 12), the period covered since the last report, the percentage of respiratory specimens testing positive for influenza viruses, a key indicator of the level of influenza activity, ranged from 17.6% (week 4) to 25.9% (week 8) (Figure 1). Since September 30, 2001, World Health Organization (WHO) and National Respiratory and Enteric Virus Surveillance System (NREVSS) collaborating laboratories in the United States tested 72,877 specimens for influenza viruses;

*WHO and NREVSS collaborating laboratories, national sentinel physician influenza-like illness tracking system, 122 Cities Mortality Reporting System, and state and local health department reporting.
†As of April 3, 2002.

FIGURE 1. Number and percentage of specimens testing positive for influenza, World Health Organization and National Enteric and Respiratory Virus Surveillance System Collaborating Laboratories — United States, 2001–02 Season*



*As of April 3, 2002.

12,017 (16.5%) were positive, of which 11,599 (97%) were influenza A viruses and 418 (3%) were influenza B viruses. Approximately one third of the influenza B viruses were isolated in the Mid-Atlantic region of the United States. Of the 3,479 influenza A viruses that have been subtyped, 3,426 (98%) were H3 viruses, and 53 (2%) were H1 viruses.

CDC has characterized antigenically 391 influenza isolates collected in the United States since September 30. Of these, 279 were influenza A (H3N2) viruses, 14 were influenza A (H1) viruses, and 96 were influenza B viruses. Of the 14 A (H1) viruses, five were A (H1N1) viruses and nine were A (H1N2) viruses. These nine A (H1N2) viruses came from patient specimens collected in Wisconsin in December 2001. Two other A (H1N2) viruses were isolated from patient specimens collected during July and September in Texas and Nevada, respectively. The influenza A (H3N2) and A (H1) viruses were similar antigenically to the vaccine strains A/Panama/2007/99 (H3N2) and A/New Caledonia/20/99 (H1N1) viruses, respectively.

Influenza B viruses currently circulating worldwide can be divided into two antigenically distinct lineages: B/Yamagata/16/88 and B/Victoria/2/87. B/Yamagata viruses have circulated widely since 1990, and the B component of the current influenza vaccine belongs to this lineage. Since 1991, B/Victoria viruses had not been identified outside of Asia. However, since March 2001, B/Victoria lineage viruses have been identified in many countries, including the United States. Of the 96 U.S. influenza B viruses characterized antigenically this season, 53 were of the B/Yamagata lineage, and 43 were of the B/Victoria lineage. Of the 53 B/Yamagata lineage viruses, 22 were similar to the vaccine strain, B/Sichuan/379/99, and 31 demonstrated reduced titers to ferret antisera produced against B/Sichuan/379/99.

During January 20–March 23, 2002, the weekly percentage of patient visits for influenza-like illness (ILI)[§] reported

[§] Temperature of ≥100.0°F (≥37.8°C) and either cough or sore throat in the absence of a known cause.

by U.S. sentinel physicians in 47 states ranged from 1.7% to 3.5%. For the week ending March 23, the percentage of patient visits for ILI was 1.7%, below the national baseline of 1.9%[¶]. During the same week, influenza activity[**] reported by state epidemiologists was widespread in three states (Arizona, Missouri, and Vermont), and regional in 17 states (California, Idaho, Illinois, Louisiana, Michigan, Montana, Nebraska, New York, Ohio, South Carolina, South Dakota, Tennessee, Texas, Utah, Virginia, Washington, and Wisconsin). Twenty-seven states, New York City, and Washington, D.C. reported sporadic influenza activity, and Alaska and Georgia reported no influenza activity. One state did not report.

During the week ending March 23, the 122 Cities Mortality Reporting System attributed 8.8% of recorded deaths to pneumonia and influenza (P&I). This percentage was above the epidemic threshold[††] of 8.2% for that week. The percentage of P&I deaths was above the epidemic threshold during weeks 9 through 12.

Reported by: *WHO Collaborating Center for Surveillance, Epidemiology, and Control of Influenza; A Postema, MPH, L Brammer, MPH, H Hall, A Klimov, PhD, K Fukuda, MD, N Cox, PhD, Div of Viral and Rickettsial Diseases, National Center for Infectious Diseases; S Harper, MD, EIS Officer, CDC.*

Editorial Note: Influenza activity in the United States during the current season increased steadily during December–January, peaked in February, and is declining nationwide. Influenza activity has peaked during February or later during 15 of the last 25 seasons. Last season, influenza activity peaked in January. In recent weeks, influenza B virus activity has increased in certain areas of the country, and both influenza A and B viruses might continue to circulate during April.

During 2001–2002, influenza A (H1N2) viruses have been isolated from several countries, including the United States (*3*). These new A (H1N2) viruses appear to have resulted from reassortment of the genes of currently circulating influenza A (H1N1) and A (H3N2) subtypes. Because hemagglutinin proteins of the A (H1N2) viruses are similar to those of the currently circulating A (H1N1) viruses, and the neuraminidase proteins are similar to those of the current A (H3N2) viruses, the current vaccine should provide good protection against the new A (H1N2) viruses (*4*). No information indicates that A (H1N2) viruses are causing more severe illness than other influenza A viruses, and no unusual increases in influenza activity have been associated with these viruses. Similar reassortment A (H1N2) viruses were isolated in China during the 1988–89 influenza season but had not been reported in other parts of the world since that time. Whether the new A (H1N2) viruses will persist is uncertain.

The Food and Drug Administration's Vaccine and Related Biological Products Advisory Committee (VRBPAC) recommended inclusion of the A/New Caledonia/20/99-like (H1N1), A/Moscow/10/99-like (H3N2), and B/Hong Kong/330/2001-like viruses in the 2002–03 trivalent influenza vaccine for the United States (*5*). The A (H1N1) and A (H3N2) components are the same as those used in the 2001–02 season vaccine. The influenza B component of the 2002–03 season vaccine is new and will be a virus of the B/Victoria lineage. The emergence of B/Victoria lineage influenza viruses around the world led to the recommended change in the B strain to be included in the 2002–03 vaccine. The B component of the current influenza vaccine is expected to provide lower levels of protection against viruses of the B/Victoria lineage.

CDC annually collects and reports U.S. influenza surveillance data during October–May. During this period, the information is updated weekly and is available through CDC voice information, 888-232-3228, fax information, 888-232-3299 (request document number 361100), or at http://www.cdc.gov/ncidod/diseases/flu/weekly.htm.

Acknowledgment

This report is based on data contributed by participating state and territorial epidemiologists and state health laboratories, WHO collaborating laboratories, National Respiratory and Enteric Virus Surveillance System laboratories, Sentinel Physicians Influenza Surveillance System, Div of Public Health Surveillance and Informatics, Epidemiology Program Office, Div of Vital Statistics, CDC.

[¶] The national baseline was calculated as the mean percentage of visits for ILI during noninfluenza weeks plus two standard deviations. Because of wide variability in regional level data, calculating region-specific baselines is not possible, and to apply the national baseline to regional level data is not appropriate.

[**] Levels of activity: 1) *no activity*, 2) *sporadic*—sporadically occurring ILI or laboratory-confirmed influenza with no outbreaks detected, 3) *regional*—outbreaks of ILI or laboratory-confirmed influenza in counties with a combined population of <50% of the state's population, and 4) *widespread*—outbreaks of ILI or laboratory-confirmed influenza in counties with a combined population of ≥50% of the state's population.

[††] The expected baseline proportion of P&I deaths reported by the 122 Cities Mortality Reporting System is projected by using a robust regression procedure in which a periodic regression model is applied to the observed percentage of deaths from P&I since 1983. The epidemic threshold is 1.654 standard deviations above the seasonal baseline. Before the 1999–2000 season, a new case definition for a P&I death was introduced. During summer 2000, the baseline and epidemic thresholds were adjusted manually to account for these changes in case definition. For the 2001–02 season, sufficient data have been collected by using the new case definition to allow projection of the baseline using the regression procedure employed before the 2000–01 season.

Suspected Cutaneous Anthrax in a Laboratory Worker — Texas, 2002

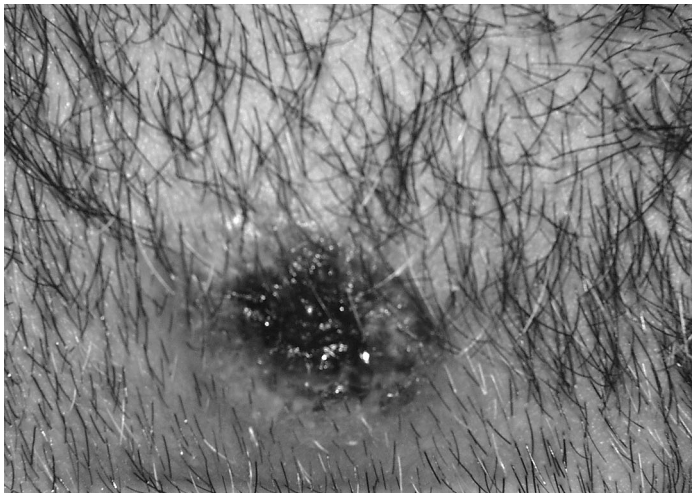
On March 6, 2002, CDC's National Institute for Occupational Safety and Health (NIOSH) received a request for a health hazard evaluation from the director of Laboratory A to assist in the evaluation of a worker who had been diagnosed with cutaneous anthrax. Laboratory A, a provisionally approved Laboratory Response Network level B laboratory, had been processing environmental samples for *Bacillus anthracis* in support of CDC investigations of the bioterrorist attacks in the United States during fall 2001. Since March 7, CDC has interviewed the ill laboratory worker and other workers at the laboratory and conducted environmental assessments of the workplace. This report summarizes the epidemiologic and environmental investigation of this case, which indicates that the likely source of exposure was the surface of vials containing *B. anthracis* isolates that the worker placed in a freezer on March 1. Laboratory workers handling specimens of *B. anthracis* should follow recommended procedures to minimize the risk of *B. anthracis* transmission and anthrax.

The laboratory worker was one of three employees of Laboratory A who had primary responsibility for processing environmental *B. anthracis* specimens. Neither this worker nor any of the other approximately 40 employees of Laboratory A had received anthrax vaccine. The laboratory worker did not handle *B. anthracis*-containing samples or cultures during February 19–28. On February 28, he cut a small bump on his right jaw while shaving, which bled briefly and then became itchy and irritated. On March 1, he assisted a co-worker moving vials containing aliquots of confirmed *B. anthracis* isolates from the biological safety cabinet (BSC) in the main laboratory to the freezer in an adjacent room. The co-worker had transferred the isolates from blood agar plates to the vials by collecting the growth with a swab. The co-worker removed the vials from the BSC and handed them to the patient. Without gloves, the patient took the vials from the co-worker, placed the vials in the freezer, and then washed his hands with soap and water. During the next 2–3 days, the worker's facial wound increased in size and developed a scab. He also reported right cervical adenopathy, a low-grade fever, and swelling and erythema on his right cheek and neck. The patient's health-care provider obtained a swab of the area underneath the scab and of the area under a vesicle, without cleansing the skin first. The health-care provider made a presumptive diagnosis of cutaneous anthrax and the patient was administered a 2-week course of ciprofloxacin.

The culture of this specimen was positive for *B. anthracis* on testing at Laboratory A and CDC. Because of culture results, the patient was admitted to the hospital on March 5 and treated with intravenous ciprofloxacin and doxycycline pending antimicrobial susceptibility testing. The lesion developed the characteristic eschar of cutaneous anthrax (Figure 1). A chest radiograph performed on admission demonstrated possible fullness of the mediastinum, but computed tomography of the chest was normal. The isolate was susceptible to ciprofloxacin and doxycycline, and the patient continued receiving ciprofloxacin. The patient's symptoms improved during hospitalization, and he was discharged on March 9. Serologic studies for antibodies to *B. anthracis* are planned.

On March 5, Laboratory A's certified industrial hygienist (CIH) performed environmental sampling of both Laboratory A and the patient's residence. Seven wipe samples were taken at the laboratory (i.e., the top of the vials the patient had handled, the key to the freezer where the vials were placed, the doorknob of the freezer room, the centrifuge where specimens are prepared, the two BSCs where specimens are handled,

FIGURE 1. Anthrax lesion on patient's right jaw



Photo/CDC File

and surfaces in the patient's office in Laboratory A), seven were taken at the patient's residence. The CIH then cleaned surfaces and equipment throughout the laboratory and the patient's residence by using a disinfectant containing a phenolic and a quaternary ammonium compound, which are not sporicidal. The environmental samples were analyzed in Laboratory A. All samples were negative except the wipe sample collected from tops of the vials that the patient had handled, which was positive for *B. anthracis*. Confirmation of the vial top specimen at CDC is planned.

Workers reported that specimen processing of environmental samples suspected of containing *B. anthracis* is done under Biosafety Level 3 (BSL-3) conditions (*1*). These samples, including swab, wipe, dust (collected onto filter media by a vacuum), and air samples, are opened in a Class II, Type A BSC in a room designated for acid-fast bacillus specimens (AFB room). Personal protective equipment (PPE) for procedures performed in this room includes disposable, fluid-resistant laboratory coats, gloves, and either a NIOSH-certified N95 or P100 disposable, filtering-facepiece respirator, which are disposed of into a biohazard container before exiting the room. Work with purified *B. anthracis* cultures is performed in a separate BSC located in the main laboratory room. PPE at this workstation consists of gloves and a laboratory coat. Aliquots of confirmed isolates of *B. anthracis* are placed in vials and stored in a locked freezer in a room located off the main laboratory. A 10% bleach solution is routinely used to decontaminate surfaces after processing specimens potentially containing *B. anthracis.* However, because bleach caused labels to become dislodged, storage vials had been sprayed with 70% isopropyl alcohol instead of being wiped with bleach. By the time of the CDC site visit, Laboratory A personnel had obtained labels for storage vials that would not dislodge with bleach.

On March 7 and 8, CDC interviewed Laboratory A workers; none reported illness among other employees or their family members. CDC also conducted environmental sampling at Laboratory A on March 7, consisting of 40 surface wipe and 36 air samples. Wipe samples obtained with sterile polyester/rayon pads, moistened with sterile water, were collected from various surfaces in the laboratory and in the adjacent office area, including desks, flooring, door knobs, BSCs, heating, ventilation, air-conditioning return air grills, and laboratory equipment (including the centrifuge and shaker used for processing environmental samples). Air samples were collected in three locations in the laboratory: the AFB room, the area adjacent to the BSC used for anthrax work, and the general microbiology area; two locations in the adjacent office area; and outdoors. All environmental samples were negative for *B. anthracis* at CDC.

On March 8, CDC performed a building assessment, including a ventilation survey, airflow distribution mapping, and BSC characterization. The AFB room was not under negative pressure in relation to adjacent areas of the main laboratory; however, the laboratory was under negative pressure relative to the outside and to the adjacent office areas. The BSCs were functioning adequately.

Reported by: *TA Mackey, PhD, University of Texas Health Science Center at Houston; EH Page, MD, KF Martinez, MSEE, TA Seitz, MPH, BP Bernard, MD, AL Tepper, PhD, Div of Surveillance, Hazard Evaluations, and Field Studies, National Institute for Occupational Safety and Health; RS Weyant, PhD, Office of Health and Safety; NE Rosenstein, MD, BA Perkins, MD, T Popovic, PhD, Div of Bacterial and Mycotic Diseases; HT Holmes, PhD, Div of Healthcare Quality Promotion, National Center for Infectious Disease; CW Shepard, MD, EIS Officer, CDC.*

Editorial Note: The findings of this investigation indicate that the worker at Laboratory A likely developed cutaneous anthrax because of skin exposure to a contaminated surface. The health hazard evaluation also identified additional steps Laboratory A should take to ensure worker safety.

Because *B. anthracis* can cause lethal infections and can form infectious aerosols, CDC and the National Institutes of Health recommend that laboratories producing quantities or concentrations of *B. anthracis* (i.e., culturing the organism for diagnostic purposes) apply practices appropriate to BSL-3 conditions (*1*). BSL-3 practices emphasize primary and secondary barriers to protect personnel in contiguous areas from exposure to potentially infectious aerosols. A vigorous program of routine decontamination with a 10% bleach solution is needed to kill viable *B. anthracis* spores on laboratory surfaces and vials. Alcohol is not sufficient to eliminate viable *B. anthracis* spores from contaminated surfaces (*2*). Gloves should be used whenever handling material that contains or might contain *B. anthracis,* and skin defects should be covered with an impermeable occlusive bandage while working in the laboratory. Work should be organized so that all *B. anthracis* sample manipulations are performed in a single room with most procedures performed in a BSC. Access to such rooms should be limited to laboratorians directly working with the samples.

The Advisory Committee on Immunization Practices developed guidelines for routine vaccination with anthrax vaccine (*3*). This suspected case of laboratory-acquired cutaneous anthrax highlights the need for anthrax vaccination, in addition to standard laboratory safety procedures, for laboratorians who work routinely with *B. anthracis* specimens.

CDC will work with state and local health departments to identify and vaccinate these laboratory workers.

This case is defined by CDC as a suspected case of cutaneous anthrax rather than a confirmed case (*4*) because processing of the swab of the lesion at the same laboratory where the suspected exposure occurred introduces the possibility of contamination of the patient's sample with *B. anthracis* from the laboratory. However, this patient's clinical syndrome and environmental exposure are consistent with cutaneous anthrax (*4*). CDC will update the surveillance status of this case as the results of other laboratory tests (e.g., serologic tests) become available.

Any exposure leading to a suspected case of cutaneous anthrax requires a public health investigation to identify other exposures in the same setting that might have led to other cases of cutaneous or inhalational anthrax. Local public health authorities should be notified immediately and appropriate laboratory procedures followed when treating clinicians suspect anthrax. This investigation did not identify inhalation exposures, and CDC does not recommend prophylaxis for the prevention of cutaneous anthrax. Active surveillance for cutaneous and inhalational disease should be ongoing among laboratorians working with *B. anthracis.*

Imported Dengue — United States, 1999 and 2000

Dengue is a mosquito-transmitted acute viral illness caused by any of the four dengue virus serotypes (DEN-1, DEN-2, DEN-3, and DEN-4). Dengue is endemic in most tropical and subtropical areas of the world and has occurred among U.S. residents returning from travel to such areas. CDC maintains a laboratory-based passive surveillance system for imported dengue among U.S. residents (laboratory-diagnosed dengue in a U.S. resident living in an area without known authochthonous dengue transmission, with travel history outside the United States in the 14 days before symptom onset). The system relies on reports by clinicians to state health departments, which forward patient specimens to CDC for diagnostic testing. This report summarizes information about imported dengue cases among U.S. residents during 1999–2000. The findings indicate that dengue continues to cause disease in U.S. travelers abroad. Travelers to tropical areas should protect themselves from mosquito bites, and health-care providers should consider dengue in the differential diagnosis of illness for patients who have returned recently from such areas.

Serum samples from 216 persons who had suspected dengue on the basis of clinical presentation and onset of symptoms in 1999 and 2000 were submitted to CDC from 34 states and the District of Columbia (*1*). From these samples, 41 (19%) cases were laboratory-diagnosed as dengue, of which 38 (93%) had IgM antibody or single high titers of IgG antibody in serum samples, and three (7%) patients had isolation of dengue virus (DEN-2, DEN-3, and DEN-4; one case each) (Table 1). Dengue diagnosis was negative in 112 (52%) patients, and indeterminate among 63 (29%) patients because convalescent samples for serologic testing were unavailable.

Of the 40 laboratory-diagnosed dengue cases with available data, 22 (55%) were males. Age was reported for 35 persons (median: 37 years, range: 5–72 years). Clinical information was available for 28 patients with laboratory-diagnosed dengue. The most commonly reported symptoms were fever (100%), headache (64%), rash (54%), and myalgia (39%). At least three patients were identified as having been hospitalized, and one of these died (a male aged 41 years who had recently returned from Bangladesh).

States reporting the highest number of cases were Massachusetts (four) in 1999 and New York (five) in 2000. Travel histories within the 2 weeks before illness, available for 33 persons, indicated that infections probably were acquired in Asia (13 cases), the Caribbean islands (12), Central America (seven), South America (one), and Africa (one). One patient reported traveling both in the Caribbean islands and South America.

Data for both 1999 and 2000 indicated a marked decline in persons tested and in the percentage of persons laboratory-diagnosed with dengue, compared with 1997 and 1998, when 349 persons were tested and 143 (41%) were laboratory-diagnosed with dengue (*2*).

Reported by: *GG Clark, PhD, JG Rigau-Pérez, MD, V Vorndam, PhD, Div of Vector-Borne Infectious Diseases, National Center for Infectious Diseases; JM Hayes, DrPH, EIS Officer, CDC.*

Total	**101**	**20**		**115**	**21**	

* Not including 66 (14.3%) laboratory-positive dengue patients out of 462 suspected cases identified in 1999 by the Texas laboratory-based active surveillance system.

Editorial Note: Dengue is transmitted to humans by *Aedes* mosquitoes. The majority of U.S. residents with dengue become infected during travel to tropical areas, although autochthonous transmission of dengue was documented in Texas in 1999 (*3*,*4*), and Hawaii in 2001 (*5*). The 1999 Texas outbreak was limited in scope because environmental factors (e.g., air conditioning) limited contact with *Ae. aegypti* mosquitoes. In Hawaii, the outbreak might have been limited because the vector was *Ae. albopictus*, a less efficient vector for dengue than *Ae. aegypti*, which was not detected in localities where dengue transmission occurred.

The incubation period of dengue has a range of 3–14 days (in the majority of cases, 4–7 days). Dengue virus infection can be asymptomatic or cause illnesses ranging from mild undifferentiated fever to severe disease, including hemorrhagic manifestations and shock (*6*). Dengue hemorrhagic fever (DHF) is characterized by fever, minor or major bleeding phenomena, thrombocytopenia (≤100,000 platelets/mm^3), and evidence of increased vascular permeability (e.g., hemoconcentration [hematocrit increased by ≥20% from baseline], pleural or abdominal effusions, or hypoproteinemia) (*6*). Dengue shock syndrome (DSS) is DHF with signs of circulatory failure, including narrow pulse pressure (≤20 mmHg), hypotension, or shock, and might result in a case fatality rate of approximately 10% (*7*).

During 1993–1998, the number of imported laboratory-diagnosed U.S. cases increased, reflecting the impact of travel and the occurrence of epidemic dengue in 1995 and 1998,

especially in the Caribbean and Central America. The smaller number of laboratory-diagnosed cases of dengue in 1999 and 2000 is temporally associated with a decreased number of cases of dengue/DHF in the Americas (*8*).

The findings in this report are subject to at least two limitations. First, travel histories and clinical information were available only for certain persons with dengue, and they might not be representative of all persons with imported dengue. Second, the number of dengue cases referred to CDC for diagnosis represents a minimum estimate of the actual number of U.S. travelers with dengue fever or DHF/DSS. Diagnostic samples might not have been sent for testing or might have been sent to other laboratories. Because dengue is not nationally reportable, persons with suspected dengue might not be reported. For example, in response to the 1999 documented authochthonous transmission of dengue, Texas implemented a state laboratory-based active surveillance system. Of the 462 patients whose specimens were submitted for testing at the Texas Department of Health (TDH) or other reference laboratories that year, 66 (14.3%) were laboratory-diagnosed as dengue (TDH, surveillance data, cases not included in this report).

Persons traveling to areas where dengue is endemic should avoid exposure to mosquitoes by using repellents, wearing protective clothing, and remaining in well-screened or air-conditioned areas. No vaccine is available for preventing dengue infection. Health-care providers should consider dengue in the differential diagnosis of illness for all patients who have fever and a history of travel to tropical areas within 2 weeks before the onset of symptoms. Supportive measures should be administered, and only acetaminophen is recommended for management of pain and fever. Acetylsalicylic acid (i.e., aspirin) and other nonsteroidal anti-inflammatory agents are contraindicated because of their anticoagulant properties. Dengue patients should be monitored for signs of DHF, especially hypotension, because prompt fluid therapy reduces morbidity and mortality. Acute-phase (0–5 days after onset of symptoms) and convalescent-phase (6–30 days after onset of symptoms) serum samples obtained for viral isolation and diagnosis should be sent through state or territorial health departments to CDC's Dengue Branch, Division of Vector-Borne Infectious Diseases, National Center for Infectious Diseases, 1324 Calle Cañada, San Juan, PR 00920-3860, telephone 787-706-2399, fax 787-706-2496. Serum samples should be accompanied by a summary of clinical and epidemiologic information, including date of onset of disease, date of collection of sample, and a detailed recent travel history.

U: Unavailable. -:No reported cases.

* Mortality data in this table are voluntarily reported from 122 cities in the United States, most of which have populations of ≥100,000. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.

† Pneumonia and influenza.

§ Because of changes in reporting methods in this Pennsylvania city, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.

¶ Total includes unknown ages.

All *MMWR* references are available on the Internet at http://www.cdc.gov/mmwr. Use the search function to find specific articles.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

References to non-CDC sites on the Internet are provided as a service to *MMWR* readers and do not constitute or imply endorsement of these organizations or their programs by CDC or the U.S. Department of Health and Human Services. CDC is not responsible for the content of pages found at these sites. URL addressess listed in *MMWR* were current as of the date of publication.

The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format and on a paid subscription basis for paper copy. To receive an electronic copy on Friday of each week, send an e-mail message to *listserv@listserv.cdc.gov*. The body content should read *SUBscribe mmwr-toc*. Electronic copy also is available from CDC's World-Wide Web server at *http://www.cdc.gov/mmwr* or from CDC's file transfer protocol server at *ftp://ftp.cdc.gov/pub/Publications/mmwr*. To subscribe for paper copy, contact Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone 202-512-1800.

Data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the following Friday. Address inquiries about the *MMWR* Series, including material to be considered for publication, to Editor, *MMWR* Series, Mailstop C-08, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333; telephone 888-232-3228.
